Abstract: A soluble molecular analogue of photoresponsive Co/Fe Prussian blues is described within this report. As judged via a variety of spectroscopic, magnetic, and crystallographic methods, electron transfer within the octanuclear complex (below 250 K) converts paramagnetic red crystals into green diamagnetic ones. The color and magnetic changes are associated with the transformation of FeIII LS-CN-CoII HS units into FeII LS-CN-CoII LS fragments in manner that is identical to that found for the A6[Co(OH2)(6-x)Fe(CN)x]eH2O (A6 = alkali metal cation) family of three-dimensional Prussian blues. Moreover, this intramolecular electron transfer can be quantitatively circumvented via rapid thermal quenching and reversed via simple white light irradiation at low temperatures. Remarkably the data suggests that thermally or photoinduced paramagnetic metastable phases are identical and exhibit long relaxation times that approach 10 years at 120 K.

Introduction

Over the past decade there has been considerable interest in the development of tunable molecule-based materials that exhibit bistability in their physical properties as a function of external stimuli. Under ideal conditions such materials may allow for the construction of energy-efficient, switchable molecule-based information storage or electronic devices, assuming that the molecules can be properly addressed in electronic circuits.1,2

In 1996, Hashimoto and co-workers3 first described that reversible magnetization changes could be photochemically induced in a magnetic molecule-based Prussian blue analogue of K0.14Co[Fe(CN)6]0.71H2O stoichiometry. The compound adopts a face-centered cubic structure consisting of Fe-CN-Co linkages and exhibits an intense metal-to-metal charge transfer absorption in the visible region, ascribed to the conversion of FeII-CN-CoIII to FeIII-CN-CoIII units via electron transfer.3 The electron transfer can be either thermally or photochemically initiated affording dramatic changes in the magnetic and optical properties exhibited by the lattice. For example, red light irradiation (660 nm) increases the ferrimagnetic ordering temperature from 16 to 19 K and a concomitant increase of the magnetization is observed. This effect is ascribed to the phototransformation of diamagnetic FeII LS (low-spin, t2g6)-CN-CoIII HS (high-spin, t2g5e5g) one, and can be reversed via blue light irradiation (450 nm) or heating of the sample above 150 K, affording FeIII LS (μ-CN)CoII HS (Scheme 1) linkages.3 At temperatures below ca. 150 K, most of the material contains diamagnetic FeII LS (μ-CN)CoII LS units.

Subsequent reports by Verdaguer and Hashimoto described that the photomagnetic behavior of these Co/Fe Prussian blues can be systematically tuned via alteration of the Co/Fe ratio present in the nonstoichiometric A6[Co(OH2)(6-x)Fe(CN)x]eH2O (A6 = alkali metal cation) lattices.4–14 When m < 1, the

structures, spectroscopic properties, and magnetic behavior of an octanuclear \(\{\text{Fe}^{III}\text{Co}^{II}\}\) complex (1) that exhibits reversible intramolecular charge transfer as a function of temperature and light irradiation.

**Experimental Section**

**Materials.** All operations were conducted under an argon atmosphere by using standard Schlenk and drybox techniques. Transfers of solutions were carried out through stainless steel cannulas. Solvents were distilled under dinitrogen from CaH\(_2\) (acetonitrile and dichloromethane), Mg turnings (methanol), or sodium-benzophenone (diethyl ether) and sparged with argon prior to use. Dimethylformamide (DMF) was dried using Linde 13X molecular sieves and sparged with argon before use. The preparation of \(K[pzTp]^{2+}\)\(\text{Fe}^{III}\), \(2\) \(2.2.2\)-tris(pyrazolyl)-ethanol, \(2\) \(\text{[NEt}_4\text{]}\)(\(\text{pzTp}\text{Fe}^{III}\text{CN})_3\), and \(\text{[NEt}_4\text{]}\text{CN}\) were described elsewhere. \(\text{Co(ClO}_4\text{)}_2\cdot6\text{H}_2\text{O (Baker)}\) and aqueous \(30\% \text{H}_2\text{O}_2\) (Aldrich) were used as received.

**Physical Methods: IR and UV–Visible Spectroscopies.** The IR spectra were recorded as Nujol mulls between KBr plates on a Mattson Galaxy 5200 FTIR instrument. UV–vis spectra were recorded under dinitrogen using a Shimadzu UV-2501 PC UV–vis recording spectrophotometer. Variable temperature IR and UV–vis data were collected using a liquid nitrogen cooled Glaseby Specac Variable Temperature Cell (KBR windows) and controller operating between 77 and 300 K.

**Physical Methods: Differential Scanning Calorimetry.** Differential scanning calorimetry (DSC) measurements were conducted on a Perkin-Elmer Pyris apparatus using closed aluminum pans containing a polycrystalline sample of \(1\) (31.86 mg). Thermal equilibration was verified at the starting and final temperatures of each scan using 1 min isotherms with measurements repeated at various scan rates (10, 5, and 2 K min\(^{-1}\)). Temperature and enthalpy calibrations were performed using an indium reference sample. An average transition enthalpy of +56(4) kJ mol\(^{-1}\) was deduced via integration of the DSC peak after a polynomial baseline correction (Supporting Information, Figure S1, left, 2 K min\(^{-1}\)). Transition temperatures (254 K when cooling, 256 K when heating) were obtained by extrapolating the peak maxima temperatures to a zero scan rate (Supporting Information, Figure S1, right).

**Physical Methods: Surface Reflectivity.** The optical reflectivity properties of \(1\) under white-light irradiation (90(10) mW cm\(^{-2}\)) have been investigated using a home-built reflectivity system composed of a CVI spectrometer and three optical fibers: two for incident light (white light irradiation and analysis) and one for outgoing spectral analysis. The reflectivity signal was referenced to two standards: barium sulfate for the white color (\(R = 1\), Abs. = 0) and activated charcoal for the black color (\(R = 0\), Abs. = 1). This experimental setup allows for the collection of absorption spectra, between 500 and 900 nm in a temperature range of 10–290 K (3 K min\(^{-1}\)), while simultaneously observing the temperature dependence of the reflectivity signal at two different wavelengths (±2.5 nm). To avoid solvent loss, \(1\) was introduced into the sample chamber under a He atmosphere at 220 K.

**Physical Methods: Magnetic and Photomagnetic Studies.** Magnetic and photomagnetic measurements were obtained using a Quantum Design MPMSS-XL SQUID magnetometer residing at the Centre de

**Scheme 1.** Thermally and Photoinduced Intercalation of \(\text{Fe}^{III}(\mu-\text{CN})\text{Co}^{III}\) and \(\text{Fe}^{III}(\mu-\text{CN})\text{Co}^{II}\) Units

Fe sites are fractionally occupied and the Co centers concomitantly contain one or more water molecules to satisfy their coordination spheres. The number of coordinated water molecules, which is related to the number of low-spin [Fe(CN)_6]\(^{3-}\) vacancies, act to tune the ligand field strengths and redox potentials of the Co centers; in these solids an average CoN\(_2\)O coordination environment and adjacent light-sensitive [Fe(CN)_6](-) sites are paramount for engineering lattices that exhibit reversible photoinduced magnetization changes.\(^1\)

However while the optical and magnetic properties of Co/Fe Prussian blue analogues can be systematically tuned via stoichiometrically controlled alkali metal cation insertion, (resulting in defect lattices that are inherently nonstoichiometric), systematic structure–property studies become difficult at best. Therefore an active trend in cyanometalate research has been directed toward the synthesis of soluble and well-defined photoresponsive compounds via judicious choice of molecular building blocks. Using a building block synthetic strategy, self-assembly of cyanometalate anions and coordinatively unsaturated transition-metal cations can be utilized to generate discrete polynuclear products containing Fe(µ-CN)Co linkages; examples include di-[FeCo],\(^15\) tetra-[FeCo],\(^16\) and penta-nuclear [FeCo]\(^{17-19}\) complexes, respectively. However, to the best of our knowledge, photomagnetic bistability has not been reported for these molecular complexes.

To this end, we have sought to prepare soluble molecular analogues of photoresponsive Prussian blues, using facially coordinate organic capping ligands to control the directionality and numbers of bridging cyanides and to mimic the cubic architecture of the lattice. In the present report we describe the

\(^{(22)}\) \(\{\text{pzTp}\text{Fe}^{III}\}\) is prepared as a precipitate in high yield via treatment of \(\text{Fe}^{III}\)\(\text{O}(\text{Ac})\text{Cl}\cdot3\text{H}_2\text{O}\) with 2.1 equiv of \(\text{K[pzTp]}\) in acetonitrile under an argon atmosphere.

The magnetic moment of the sample holder (plastic bag) and possible solvent loss. When the sample chamber temperature became constant (100 K) the magnetometer was purged in preparation for subsequent measurements. Magnetic data were corrected for the diamagnetism of the sample holder (plastic bag) and 1. Diamagnetic correction for 1 was estimated using Pascal’s constants.26

The photomagnetic irradiation of samples utilized a 150 W halogen/tungsten lamp (LEICA CLS 150XD) that was directed into the magnetometer cavity via an optical fiber. Finely ground crystals of 1 (1.25, 1.96, 3.27, and 2.81 mg) were packed into a ca. 10 mg capacity Teflon cup (3 mm diameter) in direct contact with the optical fiber (on top of cup). The residual magnetic signal of the Teflon sample holder was previously determined and found to be of the same magnitude as the instrumental magnetization noise; consequently no diamagnetic correction for the sample holder was applied to the raw magnetic data collected. The incident light intensity power was determined ex-situ to be 575(40) mW cm⁻². All temperatures were corrected for sample heating (via incident white light) relative to those obtained in the absence of light. Desexcitation of the photoinduced and quenched states by heating (via incident white light) relative to those obtained in the absence of light.

Results and Discussion

Synthesis, Crystallographic Studies, and Spectroscopic Characterization. Compound 1, [(pzTp)FeIII(CN)₃]₂[CoII(pz)₃CCH₂OH]₄[ClO₄]₄·13DMF·4H₂O, was prepared23 via treatment of equimolar quantities of [NeT₄][CoII(pz)₃CCH₂OH]₄[ClO₄]₄ (pTz = tetrapyrazolylborate) with cobalt(II) perchlorate in N,N'-dimethylformamide, followed by the addition of 2,2,2-tris(pyrrozolyl)ethanol (pzmCH₂OH).23 Compound 1 crystallizes as a red cationic octanuclear complex in the monoclinic P2₁/c space group. The octanuclear core of 1 consists of a slightly distorted [Fe₅Co₅] box in which cobalt and iron centers reside in alternate corners and are linked via cyano bridges along the cube edges (Figure 1, left); charge balancing perchlorate anions and interstitial solvent molecules keep the cationic [Fe₅Co₅] boxes well-separated from each other. The remaining three coordination sites on the Fe and Co centers are satisfied by facially coordinate pTz⁻ and pzmCH₂OH ligands, respectively, affording Fe₅Co₅ and Co₅N₉ coordination environments.

Crystallographic Studies. Crystallographic data collected for rapidly cooled crystals of 1 suggest that the metrical parameters are comparable at 260 and 90 K, respectively. At 260 K (Figure 1, left), the average Fe–C and Co–N cyanide bond distances are 1.920(8) and 2.063(7) Å, respectively, while the C–Fe–C and N–Co–N bond angles are respectively 87.8(3) and 92.5(3)° (Tables 1 and 2). Valence sum bond analysis and charge compensation indicate that the cobalt centers are high-spin and in the divalent state, while the iron centers are trivalent, forming CoII(pTz)₃FeIII linkages: the average face (Fe1⋯Fe4), edge (Fe1⋯Co4), and body diagonal (Fe1⋯Co3) distances are 7.465(5), 5.108(7), and 8.887(7) Å, respectively. In comparison, the X-ray data suggests that for quickly cooled crystals of 1 (cold

N2 gas; 300 → 90 K (at 1 K min−1) the average metal coordination spheres of these thermally quenched crystals are nearly identical to those seen at 260 K (Table 2; Supporting Information, Figure S2).

However, when crystals of I are slowly cooled from 260 to 90 K (at 1 K min−1) in the absence of light, their color changes from red to green and the average Co–N bond distance shortens by ca. 0.2 Å (Figure 1, right; Tables 1–2; Supporting Information, Figure S2). These slowly cooled crystals (90 K) exhibit (i) Co–N bond distances between 1.892(7) and 1.915(7) Å [1.905(7) Å avg] and are in the range expected for CoIII,N-S-N units; (ii) Fe–C distances that range from 1.880(8) to 1.92(1) Å [1.90(1) Å avg] and are similar to those in the 260 K structure, despite a formal iron oxidation and spin state change (e.g., FeIILS → FeIIIS). The (Fe2⋯Fe4) edge (Fe2⋯Co2), and body diagonal (Fe2⋯Co3) distances of 7.018(8), 4.963(8), and 8.583(8) Å are found, respectively. Although the space group remains the same for both temperatures (P2_1/c), a phase transition at 255 K was nevertheless confirmed by the presence of an endothermic peak (+56(4) kJ mol−1) in the differential scanning calorimetry (DSC) data (Supporting Information, Figure S1). These temperature-dependent structural variations seen in crystals of I suggest that intramolecular electron transfer converts FeIIIILS(μ-CN)CoIIIS units into FeIIILS(μ-CN)CoIIIS ones.

Spectroscopic Characterization. Additional support for this intramolecular electron-transfer hypothesis can be found in temperature-dependent infrared (IR) spectroscopy studies of I (Figure 2) conducted between 300 and 77 K. Indeed at room temperature, the cyano stretching absorption (νCN) in I is shifted to higher energy (2168 cm−1) relative to those in [NEt4][pzTp]-FeIIILS(μ-CN)_3 (2115 cm−1) and [NEt4][pzTp]FeIIILS(μ-CN)_3 (2069 and 2050 cm−1), confirming the presence of bridging cyanides within FeIIILS(μ-CN)CoIIIS linkages.17–19 Between 250 and 190 K the high-energy νCN (2168 cm−1) stretch disappears with decreasing temperature as new low-energy stretches grow in

(33) See the Supporting Information.
These absorptions are decreases in intensity as a new one appears at ca. 670 nm in 256 J. AM. CHEM. SOC. 50 and 280 K spectra; of these optical measurements can be seen when comparing the absorption appears at ca. 700 nm. The most intriguing aspect as the temperature is lowered from 280 to 160 K, a broad optical properties of white light irradiation between 280 and 50 K confirm that the facile electron transfer occurs at temperatures below ca. Solid-state spectra collected between 300 and 77 K confirm that the absorbances (2112, 2127, 2145 cm\(^{-1}\)) are in the energy range expected for cyanometalate compounds. Moreover, these temperature-induced changes in the infrared spectra of \(\text{I} \) are completely reversible upon warming samples above ca. 248 K, indicating that the bonding and/or electronic environments of the cyanide ligands change consistently with the transformation of \(\text{Fe}^{II}_{LS}(\mu\text{-CN})\text{Co}^{II}_{LS}\) units (\(T < 248 \text{ K}\)) into \(\text{Fe}^{III}_{LS}(\mu\text{-CN})\text{Co}^{I}_{HS}\) ones (\(T > 248 \text{ K}\), Figure 2).

Further experimental support for intramolecular electron transfer in \(\text{I}\) is found in the temperature dependence of the UV-visible electronic spectra in both solution (in CH\(_3\)CN) and solid states (as Nujol mulls; Supporting Information, Figures S3 and S4).\(^{33}\) At 298 K solutions of \(\text{I}\) exhibit a broad and intense absorption at 440 nm (\(\epsilon_{M} = 7077 \text{ M}^{-1} \text{cm}^{-1}\)) that is ascribed as a spin- and Laporte-allowed ligand-to-metal charge-transfer transition. A shoulder at 510 nm (\(\epsilon_{M} = 4234 \text{ M}^{-1} \text{cm}^{-1}\)) is also detected and is tentatively assigned as a metal-to-metal charge-transfer transition (Supporting Information, Figure S3).\(^{1,3}\) Solid-state spectra collected between 300 and 77 K confirm that facile electron transfer occurs at temperatures below ca. 250 K in \(\text{I}\). For example at 223 K, the absorption at ca. 420 nm decreases in intensity as a new one appears at ca. 670 nm (Supporting Information, Figure S4).\(^{33}\) These absorptions are close to those exhibited by a series of photoresponsive Co/Fe Prussian blues.\(^{5,6}\)

Accordingly, the solid-state reflectivity spectra collected under white light irradiation between 280 and 50 K confirm that the optical properties of \(\text{I}\) change with temperature (Figure 3, left).\(^{33}\) As the temperature is lowered from 280 to 160 K, a broad absorption appears at ca. 700 nm. The most intriguing aspect of these optical measurements can be seen when comparing the 50 and 280 K spectra; they are nearly identical. Further investigation of this unusual behavior is more clearly seen in plots of the surface reflectivity at 700 nm as a function of temperature (Figure 3, right). At 700 nm, the reflectivity rapidly decreases between 280 and 150 K, but quickly returns to values nearly identical to those seen at 300 K. This reproducible behavior is probably associated with light-induced conversion (below ca. 180 K) of \(\text{Fe}^{III}_{LS}(\mu\text{-CN})\text{Co}^{II}_{LS}\) units into \(\text{Fe}^{III}_{LS}\text{Co}^{I}_{HS}\) pairs, while at higher temperatures (between 200 and 250 K) the \(\text{Fe}^{III}_{LS}(\mu\text{-CN})\text{Co}^{I}_{HS}\) units are thermally transformed into \(\text{Fe}^{II}_{LS}\text{Co}^{III}_{LS}\) pairs. Such behavior has been observed in X-ray and IR studies of \(\text{I}\) and is reminiscent of several photoresponsive iron(II) spin-crossover complexes.\(^{36,37}\)

**Magnetic Studies.** To further investigate the apparent intramolecular electron transfer and spin-state changes in \(\text{I}\), we measured the magnetic properties as a function of temperature and light exposure. The temperature dependence of the susceptibility (\(\chi\)) has been investigated using a commercial SQUID magnetometer (Quantum Design MPMS-XL). Between 300 and 265 K the \(\chi T\) product remains nearly constant (12.7 cm\(^3\) K mol\(^{-1}\)) in excellent agreement with the value expected for a 4:4 ratio of magnetically isolated low-spin \(\text{Fe}^{III}\) (\(S = \frac{1}{2}, g \approx 2.7\)) and high-spin \(\text{Co}^{II}\) ions (\(S = \frac{1}{2}, g \approx 2.3\)) centers (Figure 4, left). Slowly decreasing the temperature (0.4 K min\(^{-1}\)) from 265 to ca. 255 K affords a monotonic decrease in the \(\chi T\) values, quickly approaching 0.57 cm\(^3\) K mol\(^{-1}\) at 200 K. Surprisingly, repeated cycling of the temperature between 200 and 270 K (at 0.2 to 1 K min\(^{-1}\)) leads to perfectly reproducible data without detectable thermal hysteresis. As already suggested by the structural, spectroscopic, and optical measurements of \(\text{I}\), this magnetic feature is clearly associated with an electron-transfer process that transforms \(\text{Fe}^{III}_{LS}(S = \frac{1}{2})\) and \(\text{Co}^{II}_{HS}(S = \frac{1}{2})\) metal ions into diamagnetic \(\text{Fe}^{II}_{LS}\) and \(\text{Co}^{III}_{LS}\) (\(S = 0\)) centers. In addition the small residual paramagnetism seen below ca. 200 K is likely due to \(\text{Fe}^{III}_{LS}\) and \(\text{Co}^{I}_{HS}\) ions (ca. 4.5%) that were trapped either during the structural-electronic transition or via crystallographic defects present in crystals of \(\text{I}\).

To probe the possibility that high temperature paramagnetic states can be trapped, samples were rapidly cooled (30 K min\(^{-1}\)) from 300 to 5 K, and their magnetic data collected. As judged from the \(\chi T\) vs \(T\) data, rapidly quenched samples exhibit \(\chi T\) values that are comparable to those seen for the high-temperature phase (Figure 4, left), suggesting that the electron-transfer process was thermally frozen. However below 16 K, this quenched metastable phase exhibits antiferromagnetic three-dimensional order (associated with sharp decrease of \(\chi T\) below ca. 30 K; Supporting Information, Figure S5) that is probably induced by magnetic interactions between adjacent magnetic \(\{\text{Fe}^{III}_{LS}\text{Co}^{I}_{HS}\}\) complexes.\(^{38}\) Furthermore, this apparent antiferromagnetic phase is identical to the one seen for samples of \(\text{I}\) after white light irradiation (below 100 K) of the thermodynamic and diamagnetic \(\{\text{Fe}^{III}_{LS}\text{Co}^{II}_{LS}\}\) state (Supporting Information, Figure S6).\(^{33}\) After irradiation at 30 K for 20 h, photoinduced electron transfer is nearly complete (Supporting Information, Figure S7) suggesting that the diamagnetic \(\{\text{Fe}^{III}_{LS}\text{Co}^{II}_{LS}\}\) complexes have been transformed into paramagnetic \(\{\text{Fe}^{III}_{LS}\text{Co}^{I}_{HS}\}\) ones (Figure 4, left).\(^{33}\)

These results strongly suggest that intramolecular electron transfer observed for \(\text{I}\) at 250 K can reversibly convert

**Figure 2.** Infrared spectra of \(\text{I}\) at 298 (red), 248 (green), and 193 K (black).
paramagnetic $\{\text{Fe}^{\text{III}}\text{Co}^{\text{II}}\}_x$ complexes into diamagnetic $\{\text{Fe}^{\text{II}}\text{Co}^{\text{III}}\}_x$ boxes, both as a function of temperature and light. For rapidly cooled samples of $I$, it is likely that there is insufficient thermal energy to accommodate the dramatic changes in metal–ligand bond distances upon electron transfer, and a trapped $\{\text{Fe}^{\text{III}}\text{Co}^{\text{II}}\}_x$ state is obtained. Remarkably, gradually increasing the temperature at a rate of 0.4 K min$^{-1}$ allows the thermally quenched metastable $\{\text{Fe}^{\text{III}}\text{Co}^{\text{II}}\}_x$ state to relax into the diamagnetic $\{\text{Fe}^{\text{II}}\text{Co}^{\text{III}}\}_x$ one, for temperatures up to an impressive 180 K; white light irradiation or thermal quenching of $I$ can regenerate the initial $\{\text{Fe}^{\text{III}}\text{Co}^{\text{III}}\}_x$ metastable state. 39

The most important feature of the metastable state (obtained by thermal quench or photoirradiation) is its lifetime. Surprisingly the rate at which the $\chi T$ product relaxes toward zero (the diamagnetic state) appears to be independent of how samples of $I$ were quenched and are identical to the rates estimated for the decay of the photoinduced state. For example, the time it takes for the $\chi T$ value to approach zero has been determined at 300 K and 575(40) mW cm$^{-2}$ for 20 h (left). $\chi T$ vs $T$ data (blue dots) after thermal quenching of $I$ from 300 to 5 K. The lines are guides for the eye. Relaxation time ($\tau$) vs $T^{-1}$ emphasizing thermally activated behavior of $\tau$ in $I$ (red line, right).

In other words, we propose that the thermally quenched and photoinduced states exhibit the same relaxation times and are identical in $I$. To our knowledge photoinduced magnetic relaxation times in CoFe Prussian blues have been analyzed only for $\text{Na}_{0.32}\text{Co[Fe(CN)}_6\text{]}_0.74\cdot3.4\text{H}_2\text{O}$ that displays an activation energy barrier to electron transfer ($\Delta$) of 3110(60) K and $\tau_0 = 6.7 \times 10^{-7}$ s$^{11,27}$ The three-dimensional Prussian blue $\text{Na}_{0.32}\text{Co[Fe(CN)}_6\text{]}_0.74\cdot3.4\text{H}_2\text{O}$ exhibits $\tau \sim 33$ h while the molecular analogue $I$ exhibits a surprisingly long relaxation lifetime of $\tau \sim 10$ yr at 120 K.

Conclusions. In summary, we have demonstrated for the first time that a soluble molecular analogue of three-dimensional Fe/Co Prussian blues can exhibit both thermally and photoinduced reversible electron transfer. Evidence in support of this claim was obtained via extensive X-ray crystallographic, spectroscopic, and magnetic characterization methods. The data suggest that a well-defined octanuclear complex exhibits efficient electron transfer below 250 K, converting paramagnetic $\{\text{Fe}^{\text{III}}\text{Co}^{\text{II}}\}_x$ cages into diamagnetic $\{\text{Fe}^{\text{II}}\text{Co}^{\text{III}}\}_x$ ones. Upon electron-transfer dramatic changes in molecular structure as well as the electronic, optical, and magnetic properties are observed in $I$ and can be triggered via temperature changes and/or exposure to light. We postulate that the extremely long relaxation times of the thermally and/or photogenerated metastable state may be a useful property that can be utilized in the construction of functional molecule-based electronic devices.$^{24,40,41}$

(39) Desexcitation of the photoinduced state has been attempted without success using narrow-band irradiation between 420 and 550 nm.
